### Abstract

The resurrection of essentialist arguments, in the context of the modern evolutionary synthesis, highlights the need for a break from historical definitions of *kind* and *essence* in order to bring a new paradigm in which these terms are used to conceptualise and understand evolutionary processes. The definition of essence is herein divided into two distinct parts, namely the structural essence, which is mutable and has an evolutionary context, and the character essence, which is the immutable spatiotemporal expression of the structural essence as an individual. In contrast, the kind is herein redefined as a region within a wider phylogenetically constrained organism state that reflects a conflux of character essences that form an immutable semaphoront. This organism state enables the hypothetical delineation of spatiotemporally immutable forms, called species, which are drawn from an evolutionary continuum. These revised definitions and the taxonomic clades derived from them, determine the species that can be used in the construction of phylogenies that reflect true historical and evolutionary relationships between organisms. This paper also argues that there is a need of obtaining universality in species demarcation. Allowing taxonomists to choose the appropriate concept enables the evolutionary significance of the organism to be explained and refocuses the argument from the concept back to the criteria. Essentialistic pluralism allows the taxonomist the freedom to delineate species outside of any rigid conceptual framework. An overview of a select number of current species concepts is provided, offering these as potential choices to the pluralist. We argue for a refocusing of the species debate on criteria rather than concept, thereby highlighting the real with the context of the hypothetical nature of species. Finally, we will examine the complexity of species demarcation, noting the continuing failure for explicitness in conceptual application. Finally, we argue that essentialistic pluralism is a means of achieving the gold standard for universality through its refocus of the species debate on criteria rather than concept, and thereby highlighting the hypothetical nature of species.

**Key words** Essentialism, evolution, taxonomy, kind, essence, species

## Introduction

The natural world is classically ordered according to hierarchical relationships that are constructed in a manner that does not reflect modern evolutionary principles and the new biological essentialist paradigm. The historical pursuit of inferring the natural relationships between organisms is primarily a by-product of human intellectual inquisitiveness, and reflects a pseudo-theological search for understanding the natural order of life, a quest that has challenged philosophers and those interested in the sciences before the Common Era (Henry 2011; Lewis 1963). As scientific understanding and shifts in theological influence have changed over time, so to have the processes and doctrines underpinning methodical approaches among those disciplines concerned with finding an optimal system of nomenclature similarly changed (Moritz 2013).

The shift from theocratic creationism towards an evolutionary necessity in taxonomy has challenged the hierarchical orthodoxy conceptualised and instituted by Linné (1735, 1758). This challenge has led to conflict and a rigorous defence of systems of nomenclature based on personal ideology rather than theoretical optimisation (Brummitt 2002; Cantino et al. 1999). Irrespective of the ideological stance taken, any system of nomenclature needs to impart a sense of ontology, or reality, as well as possess an inherent epistemology that enables a delineation of how derived taxonomic conceptual entities reflect the taxonomic needs of the classifier (Szalay and Bock 1991). Consequently, taxonomists are drawn towards particular taxonomic schools of thought based on their personal understanding of evolutionary theory, taxonomical needs and predisposition towards an ideological stance on a particular taxonomic or species concept (Cracraft 1987).

In order to re-engage the wider scientific community in the species debate, there needs to be an acceptance that the term “species” has fundamentally differing meanings. The use of essentialistic pluralism, with its unrestricted approach to conceptualisation of what a species is, allows the taxonomist the freedom to express a unique approach to exploring phylogeny without the shackles of rigid necessity to declare adherence to a single species concept. The broader scientific community can be brought back to the species debate only when there is an acceptance that there is no correct or incorrect conceptuality in species definition, with all proposed species concepts theoretically having a usefulness (Hausdorf 2011). Many scientists have avoided species debates in evolutionary biology as a consequence of the semantics surrounding many of the current issues (Noor 2002). Much of this avoidance can also be attributed to conceptual misunderstandings and ignorance of the theoretical basis for what actually constitutes a species.

Species need to be conceptualised outside of taxonomic classificatory systems as they fall outside of systematic hierarchical arguments being fundamentally hypothetical (Dubois 2011). Although hypothetical in nature, a species hypothesis is represented by a real set of organisms. Thus because species are real entities and not just intentional meanings derived by the taxonomist they differ innately from higher classifications which are subjective in that there is no physical representation of the hypothetical rank (Ghiselin 1974; Hull 1976). This raises a point of contention: if species are real, why are many of the concepts that are used to define them based on unreal or non-causal criteria? This leads to a complexity in conceptual realisation and invariably to conceptual misunderstanding, a problem again absent in higher taxonomic arguments that have no physical reality (Stamos 2003). There is a need for criteria to give a sense of a touchstone to the real.

One of the problems with engaging a taxonomist in the species conceptual debate is that they are often at

a loss to explain their meaning of species, falling into the trap of conceptual adherence and associated rhetoric and over-looking the hypothetical nature of the reference point in nature they seek to demarcate. Such rigidity to a conceptual belief invariably ends with the taxonomist at a loss when faced with contra-arguments (Hey 2001). This adherence to a conceptual framework also loses sight of the primary mission of the taxonomist, which is, according to Mayden (1999), “to discover, describe, and classify biological diversity, regardless of how much there may really be out there”. It is also irrational for a taxonomist to bind him/herself to any particular concept due to its convenience in application or acceptance by the wider collective scientific community (Nadachowski 1993). Further, the long-term species debate has failed to annunciate the significance of the nuances of the species concept applied by the practising biologist. The application of species concepts is used to make critical decisions that affect universal biodiversity and macroecological assessments, as well as provide the support for evolutionary understanding in fields well apart from the narrow frame of their activities (Hey et al. 2003; Tan et al. 2008; Naomi 2011; Frankham et al. 2012).

Taxonomic descriptions of new species are often fundamentally flawed as there is generally no explicit statement of the species concept used to delineate the taxon (Tan et al. 2008). This lack of conceptual explicitness leads invariably to three primary errors in the systematic demarcation of species: 1) type I errors occur when there has been an overestimation of the number of species within a particular organism complex; 2) type II errors occur when the number of species in the organism-complex has been underestimated; and 3) type III errors occur when there has been a misrepresentation of the systematic relationships between the organisms within the complex (Adams 1998). This has serious implications for understanding evolutionary history, where “irrational” species could lead to a misrepresentation of the evolutionary progression of a clade (Adams 1998). When determining a species, a taxonomist has an obligation to nominate the species conceptual approach being followed, to ensure a clear understanding of the criteria that are necessary and sufficient to determine the population (Hausdorf 2011). The need for explicitness in criteria brings the theoretical species recognition problem back within the scope of the rules of nomenclature that govern the application of names (Knapp 2008). In addition, the taxonomist has an obligation to inform on the actual process of speciation that has taken place, giving insight into the ontology and causation of organismic differentiation (Miller 2001; Losos and Glor 2003). The use of essentialistic pluralism enables the taxonomist the freedom to choose a species concept that is most appropriate for the set of organisms, irrespective of definitions that may have been applied to their sister taxa.

In this paper, we differentiate the two concepts of kind and essence that have become erroneously synonymised in modern evolutionary theory. In addition, we will demonstrate that a *kind* is a part of an organism state, which is a fixed discrete entity within a spatiotemporal framework that is defined by essences. Further, we will consider the pluralist approach to understanding what constitutes an essence, and specifically describe two discrete forms of essence, namely the character essence (Box 1), which is a spatiotemporally fixed character, and the structural essence (Box 1), which is mutable and has an evolutionary context, a distinction that has yet to be fully explored within the literature. Further, this paper will demonstrate that essentialistic pluralism is the gold standard for universality and addresses the issue of species demarcation at its core: what is the intended meaning imparted by naming an organism?

Many scientists have avoided species debates in evolutionary biology as a consequence of the semantics surrounding many of the current issues (Noor 2002). Much of this avoidance can also be attributed to conceptual misunderstandings and ignorance of the theoretical basis for what actually constitutes a species. The broader

scientific community can be brought back to the species debate only when there is an acceptance that because they are hypothetical there is no correct or incorrect conceptuality in species definition, with all proposed species concepts theoretically having usefulness (Hausdorf 2011).

### **Essentialist Taxonomy**

Essentialism has a valuable role to play in providing an understanding of evolutionary processes as it offers an explanation of the evolution of both the intrinsic and extrinsic natures of taxa (Walsh 2006). Understanding the dualistic nature of taxa requires an acceptance of the evolutionary reality that organisms evolve subordinate monophyletic groups that have an ancestry determined by the linking of real organism states (Box 1) and not some evolutionary ideology (Brundin 1972). Organism states are, in turn, defined by kinds (Box 1), which are created by the congruence of structural essences (Box 1).

Many of the reviews of species concepts fail to explore essentialist arguments, or when this exploration is carried out, it is with the basic premise that all essentialist arguments are phenetic. However, one of the major failings of the essentialist approach to species criteria is the decision which species concepts are valid and, therefore, acceptable to be used taxonomically (Hey 2006). This clearly is the crux of the problem. Taxonomists fail to recognise that species have two parts: a separate criterion with the distinctive process of species delimitation often linked with the rigidity to a concept; and the conception itself, which is hypothetical (Paul 2002). The natural consequence of failing to recognise these two parts explains why the treatment of complex taxonomic clusters, such as agamics, is overlooked in conceptual formulations. It is only with essentialistic pluralism that the taxonomist is freed from the theoretical constraints of taxonomic rigidity imposed by doctrinal adherence to a single hypothetical species concept and able to explore the criteria of the real organism necessary to impart taxonomic meaning.

Kind and essence have often been used interchangeably although they are different concepts. Consequently, they have been maligned in the arguments against immutability that have been used to support the drive toward neo-Darwinism and the modern evolutionary synthesis (Mayr 1987; Amundson 1998; Okasha 2002). There has been considerable debate on the nature of what actually constitutes an essence. First, historically to taxonomists, such as Linné, the term essence simply meant that which is taxonomically useful (Winsor 2006). Second, many contemporary essentialist arguments are pseudo-Aristotelian, based on either shared salient morphology, or innate intrinsic properties that have explicit and rigid taxonomic meaning (Wallace 2002; Oderberg 2007). Third, the essence of an organism has also been linked to its genotype, which is then expressed in the observable morphological, physiological or behavioural characters it displays (Kitts and Kitts 1979). Fourth, the genotypical approach was further refined into the extended phenetical approach, where the definition of essence included ancestry and relational biology (Walsh 2006; Elder 2008). Fifth, the more minimalist approach to defining the essence, based on the character trait, is outside of historical necessity and is not intrinsic to the definition of an individual (Dumsday 2012). Finally in contrast, the phylogenetic approach seeks to shift the focus of essentialism from a categorical basis to a more historical one, thus enabling the essence to be used in evolutionary biology through the incorporation of intrinsic with extrinsic, or relational essences as part of a wider wholistic view of the organism (Devitt 2010; Dumsday 2012). Irrespective of the approach taken to defining the essence, one of the failings of these theories is the inability to distinguish

between two distinctive essence forms, namely the structural and character essences.

The structural essences of an organism state arise from the collective essence matrix, which defines the morphospace of inclusivity of the higher taxonomy to which the organism, in all possible phenotypically plastic forms and ecological boundaries, belongs. In contrast, the character essences are the immutable attributes of an individual and the spatiotemporal expression of the structural essences. Importantly, it is the character essences of a taxon that are used to provide the restricted definition of the kind within the broader organism state.

In the current essentialist debate, the concept of a kind refers to an immutable form and is linked to a particular end point in the hierarchical tree typology. Therefore, it is theoretically incorrect to refer to species in the classical sense in terms of classes of natural kinds with an implicit immutability. Rather, species should be viewed as representatives along a continuum, thus being evolutionarily plastic. Kinds need to be viewed in terms of a convergence of structural essence axes within the organism matrix that enables the discernment of a collective type with an explicit taxonomic definition, albeit at the arbitrary judgement of the taxonomist (Forey 2002). In this context, kinds represent the collection of units of change within an organism state that results from the subjective assessment of the unbroken chain of divergence (Dobzhansky 1935). The kind forms a statement of evolutionary position chosen by the taxonomist to reflect a more inclusive organism state comprised of evolving structural essences.

Mayr (1987) rejected kinds, arguing that natural kinds were sterile, and consequently, this terminology should be restricted to inanimate objects, such as metals. However, this is an incorrect assumption based on an innate restrictiveness and lack of historicity that has been applied to the classical definition of a kind. Further, Mayr's approach is a rejection of the premise that species are capable of evolving, which is not upheld under the revised definition.

### **Historical Perceptions of Species**

Darwin (1859) argued that species are arbitrary constructs of convenience selected from a fluctuating evolutionary pond of forms. This argument mirrors the belief that species are not discrete, but rather become indistinguishable within a merging metapopulation, where essences reticulate between individuals as populations (Lamarck 1801). This idea was extending in the adaptive field theories of Wright (1932) and Dobzhansky (1951) in which discernment of taxa occurs at topological peaks of adaptational success. The valleys between the combination of genes indicate a point at which a discrete organism can be delineated from one another (Dobzhansky 1951). Species, therefore, are hypothetically derived with the choice of demarcation, a decision made by the taxonomist.

The determination of a method to demarcate species has been a complex argument that lasted centuries. Species need to be contextualised as a direct and discernible product of evolution constructed on a set of unifying essences chosen by the taxonomist. This currently occurs under guides of a theoretical concept chosen by the taxonomist. It is worth noting that the word species *senso stricto* has two primary uses: it is used by taxonomists to delineate the forms within nature and create hypothetical hierarchies and, at the same time, it is used as a definition by the taxonomist to form a discernible immutable kind that acts as a hypothetical name-bearing reference point from which the process of evolution can be described (Mayr 1987, 1996; Ereshefsky 1992; Pleijel and Rouse 2000). However, a species has a unique history and forms the more inclusive individual

taxon with characteristics that are often not exhibited by the kind (Mishler and Donoghue 1982; Nixon and Wheeler 1990; Wiley 1980). In contrast, higher taxa are multidimensional, existing within a spatio-temporal continuum in which the shared characteristics, or structural essences, are acting as axes that reflect their unique evolutionary direction (Andersson 1990; Szalay and Bock 1991). When these axes converge there is a forming of a discrete kind that can be given a formal definition (Dupré 1981). Further, it is the relationships and clustering of these organism states based on shared ancestry that forms the basis for the definition of higher taxa.

The birth of a new species, or delineation of two taxa, occurs in two ways. First, via the process of heterochronic cladogenesis, where two distinctive convergences arise in the organism state and the cleavage of new identifiable species with new identified phylogenetic constraints is deemed appropriate by the taxonomist (Huxley 1957; Gould 1977; Aze et al. 2013). Second, via the process of anagenesis, where a particular set of essences consistently converge outside the parameters of the parental metapopulation, as defined by the kind, requiring a redefinition of the kind (Huxley 1957; Aze et al. 2013). While the acceptance of stasiogenesis implies that there is no multiplication of species and evolutionary failure, it may also reflect internal reticulation of the kind that reflects a convergence about a conflux of evolutionary optimisation (Huxley 1957; Crusafont-Pairó and Truylos-Santonja 1958; figure 2). This reticulation has significant implications for phylogenetic reconstruction where only one gene has been utilised and the results may only reflect gene evolution rather than the true state of the historical relationships between organisms. Evolution is more than the addition or subtraction of genetic material, but rather reflects an interaction of gene systems: the transitional valleys between gene clusterings represent taxic exploration of evolutionary possibilities rather than the initial stages of a genetic conflux giving rise to a new taxon (Dobzhansky 1951).

Notwithstanding the mode of speciation, there is a necessary need for the generation of artificial temporal evolutionary stasiogenesis for the delimitation of an organism state for the purposes of generating systematic understanding. This artificial stasiogenesis introduces an explicitness into the definition of species that then enables the production of real propositions on the historicity of the evolution of organisms. Taxa are explicitly defined in terms of kinds to avoid ambiguity and facilitate effective communication of the biological entity reflecting the convergences of the axes even if these kinds are only representative of the wider more inclusive organism state (Dupré 1981; Bryant 1996). In point of fact, kinds represent nothing more than the adaptive peaks of an organism state.

Avise et al. (1987) highlight the complexity of gaining an understanding of the evolutionary significance and determining within an organism state when, from the extrapolation of a number of microevolutionary events, macroevolution is said to have occurred. Avise et al. (1987) saw macroevolutionary patterns as a substrate that is formed by the branches and twigs of intergenerational pedigrees within the complexity of phylogeny. One of the major theoretical standards for the delineation of a species from the myriad of branching possibilities is the simultaneous establishment of joint possession of structural essences, or synapomorphies, in each line (Bremer and Wanntorp 1979). However, strict adherence to this method of differentiation has been found to be problematic in delineating when a novel structural essence, from the time of origin to fixation, gives rise to a new kind in a spatio-temporal organism state. This can be resolved by the defining of ancestry in terms of the absence of structural essences. However, the problem with this approach to the delineation of ancestor-descendant relationships is determining the temporal points of divergence, or when does an adaptive peak

deserve taxonomic isolation from its sister peaks. A particular characteristic may be more frequent in one taxon than another, absent altogether, or cryptic, and an assumption is made by the taxonomist practising a level of pattern cladistics when a new species has arisen (Brady 1982). If this is accepted, then it is the taxic homologies, which are based on descendants rather than transformational homologies that are defining the phylogeny rather than just seeking to explain the genealogy.

Taxonomists also have to deal with a level contingency in delineating taxa (Chambers 2012). There is a level of inference, based on evidence at hand that is used to generate the essences that define the organism state and then are restricted further into the kind. This involves a shift from a search for differences to an examination of commonality and the seeking of sub-patterns, or character essences, which form the conflux of axes unifying them (Kitcher 1981). The determination of which essences forms the best guide to the determination of an organism state and the kind is a matter of relational taxonomic subjectivity (Okasha 2002; Devitt 2008). This reflects the reality that structural essences are innately ambiguous comprised of an unknown number of transitions, possess an often cryptic single origin and may have undergone a level of evolutionary reversal (de Pinna 1991). Therefore, the approach taken in the determination of a discrete kind, which represents a wider organism state, will be highly dependent on the species conceptual approach that is being utilised by the taxonomist. Again, it is worth noting that the conceptual approach to species is often restricted by a rigid adherence to an ideological stance that blinds the taxonomist to the real phylogeny.

There are a plethora of rigid methodological approaches enabling discrimination of the kind. Many of these methodical approaches to species conception are based on the single individual and are mereologically formulated, and all have the underlying drive to find exclusivity in definition (Hull 1980; Kornet 1993; de Pinna 1999). This gives rise to the problem faced with the defining of the evolutionary unit and the nature of a species itself. Further, this problem can be reduced to one of taxonomic demarcation of inclusiveness once separation based on the components of the organism and this used to aggregate and generate the populations (Hull 1980). Notwithstanding the need for definitional exclusivity, species can also be considered as a set of organisms with a unique relationship that forms a natural heterogeneous individual (Kitcher 1984a; Ereshefsky 1992).

Irrespective of the species concept that is chosen by the taxonomist, there are four basic characteristics that must be met in order to fulfil the needs of communication of the natural world. First, the needs to be a reality, or an actual spatiotemporal existence, even if this is unobservable (Cracraft 1987). Second, the species needs to have a level of individuation and mutual exclusivity, enabling a demarcation of it from other organisms (Cracraft 1987; Kornet 1993). Third, there needs to be irreducibility, such that the entity cannot further be divided and therefore forms a basal unit of taxonomy (Cracraft 1987). Finally, the species must offer a level of recognisable comparability to allow for systematic evaluation and the discernment of evolutionary history (Cracraft 1987). The individualisation of a species can be problematic, particularly at the boundaries where the descriptive essences are chosen to create the definition stray from the kind obscuring the recognisable compatibility needed to generate a phylogeny. However, taxonomic realism can be achieved only when the taxonomist rejects limiting the definition of species by adherence to dogma and accepts that nature does not differentiate itself by a single unique classificatory unit or set of definitions inherent to a particular species concept (Ruse 1998). Therefore, species-as-taxon are individuals formed out of a class consisting of a population, reflecting the reality that species are a taxonomic concept and not a category (Wiley 1980).

The need to adhere rigidly to a single concept, and the ideology that once a species has been defined it is

immutable, can hinder the greater understanding of the natural world (Knapp 2008). There is a long historical acceptance that no single concept best encapsulates the idea of species, and that there is a need to utilise the way that is optimised to achieve comprehensibility and usefulness for the species that the applied concept gives rise to (Grout 1938). Therefore, the approach to defining a species and its operation must, as a priority, grant the wider community outside the realm of semantic taxonomy a greater understanding of nature (Cracraft 1987). Each of the monist species concepts relies on a single universal level of evolutionary units, but each is fundamentally unable to account for the diversity between organisms (Mishler and Donoghue 1982). It is only with a broad pluralist approach to the idea of species as the collective individual that evolutionary relationships can be explained taxonomically.

Dealing with sub-species is problematic and this is reflected in the lack of reference to them in the conceptual literature. This is in part a consequence of the definition given to these lower taxonomic ranks such as temporarily isolated populations that are arbitrarily delimited and fated to reticulate back within other lineages (Frost and Kluge 1994). However, the problem arises when the taxonomist is faced with making a subjective decision on whether a population is an arbitrary subspecies or a distinctive allopatric population with a distinctive evolutionary trajectory (Frost and Kluge 1994). This leads to the argument that subspecies are not objective concepts (Groves 2012).

The elevation of subspecies to full species ranking and redrawing existing phylogenies has consequences for the allocation of great reputational capital. This has a direct impact on all fields of biology, particularly the highly politicised areas of ecology and conservation biology (Tan et al. 2008; Frankham et al. 2012; Hey et al. 2003). Therefore, the arguments on the treatment of subspecies are even more controversial than debating any singular particular species concept, which is why it is so often omitted from species debates. Notwithstanding species are terminal in nature thus a taxonomically defined organism is a species, as it has taxonomical importance irrespective of conception.

## **Species Conceptual Overview**

The number of species concepts that are in current use is a reflection of the treatment of the level of subtle distinctive phrasing that authors apply to a preferred concept, and its conceptual refinement is reflective of the lumping and splitting debates over species themselves (Groves 2012; Mayden 1999). The major conceptual frameworks proposed to delineate a species are each subdivided *ad infinitum* by individual graduation and augmentation as taxonomists have sought theoretical ascendancy, and have been driven to find the one true universal species theory. Fundamentally, all species concepts fall into one of four categories: 1) morphological or phenetical (primarily ahistorical); 2) biological (attribute or mechanism); 3) historical (common descent as the primary delineating factor); and 4) genetic.

Phenetist, or morphological, based species concepts are those in which physical characters are utilised to formulate the fundamental division, or class, that are used to generate a species. This is fundamentally a classical approach in which there is an innate essence that distinguishes the organism (Mayr 1987). Phenetic methodologies can be divided into two schools: Typological or Linnaean Species Concepts and Morphological or Diagnostic Species Concepts.

The biological methodologies all have, at their core, a determination of species based on fitness and

inheritance. The argument may be couched in term of current or future biological isolation, depending on the methodological approach taken, or the current selective benefits a cline may have to its current environment. However, a considerable failure of the biological species methodologies is the need for the redefining of many of the currently accepted species, lumping of reticulating populations and the application of these concepts to asexual biota (Hausdorf 2011). There are four principle schools of biological speciation: Biological or Mixological Species Concepts; Behavioural or Recognition Species Concepts; Ecological or Differential Fitness Species Concepts; and Geographical Species Concepts.

The historical species concepts are based on cladistic analyses. They use cladistic tree divisions and are grounded in cleavage in the lineage of an organism, which can be traced providing a temporal aspect to the definition (Hennig 1965; Kornet 1993). Historical concepts can be divided into two approaches, one in which the continuity is the fundamental driver of differentiation, and the other in which the recognition of distinctness predominates. The distinctness of the species as individual in the historical context is conceptualised in fundamental ways such as morphologically differentiable, adaptively distinct, geologically isolated or tokogenetically isolated (Mishler and Donoghue 1982). However, even more fundamental is the decrement of species from a delimiting point of divergence, and whether the original species is said to continue is extinguished in the divergence event (Miller 2001). A secondary fundamental issue for all historical methodologies concerns the treatment of reticulation among organisms, and this gives rise to many of the symptomatic issues concerning the biological concepts (Hausdorf 2011). There are four primary schools of historical speciation: Evolutionary or Unified Species Concepts; Hennigian General Lineage Species Concepts; Historical Continuity or Purist Phylogenetic Species Concepts; Historical Tokogenesis Species Concepts; and Phylogenetic or Historical Semphoranthy Species Concepts.

Dissimilarity models have an ideology that species should be considered in terms of the smallest delineation, a mereological approach to the delineation of entities based on similarities contained within the DNA (Baker and Bradley 2006; Mishler and Donoghue 1982). Ahistorical species concepts seek to find processes of speciation that differentiate sets of organisms. Notwithstanding the approach mode to the species concept, there is an underlying commonality (intrinsic essence) based on a shared analogy and parallel evolution that creates a fundamental natural kind, which is delineated and classifiable (Hull 1987). There are four principle schools of speciation based on genetic dissimilarity: Structural Species Concepts; Genetic or Genic Species Concepts; Cohesion or Continuous Stochastic Block Model Species Concepts; and Genotypic or Functional Clustering Species Concepts.

### **The Complexity of Demarcation**

One of the challenges facing taxonomists is the determination of the level of difference that is considered significant enough to warrant the demarcation of a species from its sister taxa (Adams 1998). The adherence to a particular species concept limits the potential for the naming of new species (de Meeûs et al. 2003). Key to the determination of what constitutes a species is the understanding of the evolutionary trajectory of an organism and the level of reticulation with sister taxa that they may undergo (Adams 1998; de Queiroz 2005). However, the determination of future evolutionary trajectories is fraught with the danger of speculation, and is often undertaken with a level of subjective evidence of directional change based on comparative phylogeny (Adams

1998). There is now almost universal consensus that, irrespective of the choice of species concept chosen by the taxonomist, it is the demarcation of a distinctive evolutionary trajectory that unifies all concepts (de Queiroz 2007).

The construction of phylogeny and the determination of species are often based on the sampling of taxa from an existing preconceived pool of organisms. These pools are derived from taxonomic assumptions that are based on existing notions of what species exist and characters are drawn from a check-list of that group (Barracough and Nee 2001). This invariably opens the process of phylogenetic reconstruction to be based in the existing taxonomy, and invariably leads to the confounding and completely arbitrary splitting-lumping conundrum (Barracough and Nee 2001). The taxonomist seeks out the patterns of recurrence in nature and then makes the internal judgement of the significance of that pattern (Hey 2001). Whether species are lumped together, or the level of variation is significant to enable the distinguishing of separate entities, it is conducted at the subjective judgement of the taxonomist, and their weighting given to differing characteristics they determine to be consequential (Casanova 2013). The approach taken in the determination of consequential characteristics is often biased by the discipline or taxonomic group that the taxonomist is working with, and their need for taxonomic indicators (Kunz 2002; Frankham et al. 2012). This invariably leads to a set of conditions, or criteria, that are used to generate the concept that is applied in the species diagnosis, often to the exclusion of all other species concepts. If species are comprised of multiple populations that are spatio-temporally separated with individual destinies either to reticulate, speciate, or go extinct, then it is clear that there is no one conceptualised force that explains all the potentialities of divergence. Consequently, no one single species concept is able to encapsulate the entirety of the collective essences of the amalgamated organism clade to meet the needs of the taxonomic masses (Haveman 2013).

One major failing with a hypothetical species is the historical clustering of organisms that can be well defined and used to generate the spatio-temporal point at which a species is delimited creates the problem of omitting transitional forms (Girard and Renaud 2011). Similarly, populations may be heterospecific and may be part of more than one species by definition (González-Forero 2009). Heterospecificity is one of the major problems when demarcating the boundaries of agamic groups and is a primary reason that most species concepts omit an argument on asexuality (Hausdorf 2011; Haveman 2013).

Discrete discernment of kinds, which are sound in their spatio-temporal position and are not singularly based upon particular apomorphs, will give rise to the collective individual, and offer basal soundness to any clade (Baum and Donoghue 1995; de Queiroz and Gauthier 1994). The monist argument that pluralism leads to confusion through a lack of intrinsic meaning in the term species can be overcome when the taxonomist is explicit. The use of essentialistic pluralism delineates a set of organisms from the natural world that contains enough meaning to enable discrimination and thus allow for an organism's taxonomic discernment. It is the failing of hierarchical taxonomic theory that, even if kinds are well defined, there remains a distinct lack of evolutionary theory in the relationships between higher taxa.

## **Reviewing Pluralism**

Many of the reviews of species concepts fail to explore essentialist arguments, or when this exploration is carried out, it is with the basic premise that all essentialist arguments are phenetic. However, one of the major

failings of the essentialist approach to species criteria is the decision that species concepts are valid and, therefore, acceptable to be used taxonomically (Hey 2006). This clearly is the crux of the problem. Taxonomists fail to separate the criteria, with which involves the distinctive process of species delimitation, from the rigidity to a concept often based on the biological (Paul 2002). The natural consequence of which explains why the treatment of complex taxonomic clusters, such as agamies, is overlooked in conceptual formulations. It is only with essentialistic pluralism that the taxonomist is freed from the theoretical constraints of taxonomic rigidity imposed by doctrinal adherence to a single species concept and able to explore the criteria necessary to impart taxonomic meaning.

The pluralistic approach does not seek to tie the taxonomist down to one species concept, but rather enables a choice in definition to be applied based on the uniqueness of the characteristics of the organism as a set, and thus is an extension of the reality that taxa are entities that currently exist, or have existed, within a temporal space and are in need of demarcation and explanation (Kitcher 1984, 1984a). This temporalism must still include innate references to the organisms that are historically related, as the removal of the historical context itself reduces the meaning of species and is a major cause of inconsistency, even in the face of disconnectivity of lineages (Ereshefsky 1992). Ereshefsky (1992) noted that pluralistic species concepts allow for the coverage of the multiplicity of evolutionary forces that drive divergences, such as interbreeding, selection, genetic homeostasis, common descent and developmental and ecological isolation. This reflects the reality of the natural world. Mayr (1987, p. 149) argues that the pluralist approach failed through the inability to distinguish the species category and the species organism: “mammals, hairy caterpillars, hairy seeds of certain plants and other hairy objects, would make a legitimate set” and therefore a heterogeneous species. Mayr (1987) fails to recognise that pluralist species are discrete individuals, a collective set unbounded in time, having a real meaning used to describe the observable and not categorical abstractions. True pluralism needs to be free from any structural boundaries and overcomes the underlying complexities of the species argument to enable a taxonomist to announce a greater accuracy in the phylogenetic classificatory process. This is achieved through the enabling of individuality through the recognition of set complexity (Lomabrd et al. 2010).

Mishler and Donoghue (1982) argue that species should not be separated from higher ranks, but form a natural extension of them, and should be viewed as assemblages united by descent, not as individuals. However, the acceptance of individuality enables a line to be drawn upon which the kinds used in classification can be decided. These kinds then enable the understanding of higher ranks based on evolutionary relationships. Not accepting species as individuals means that the basis of higher taxonomy is grounded in arbitrariness and thus rendered meaningless. The term ‘exclusivity’ can be associated with kinds and is the foundation of the coalescence theory, that biological entities are closely related to a particular group and thus objectively discernible (Baum and Donoghue 1995).

Mayden (1999) conceived the consistent approach of species delimitation, in which there was an encouragement of cooperation in the understanding of diversity and for conceptual monism. At the heart of this monist approach is the recognition of the species based on a description or diagnosis that is used as the criteria for demarcation, which is then defined by a concept (Mayden 1999). However, one universal failure of species concepts is the lack of conceptual definition, which should be resolved before the population can be determined (Hausdorf 2011). This is probably more relevant to species delineation than any conceptual approach. Hey (2006) argued that “detection protocols were not concepts” and the taxonomist needs to separate the criteria for

delineating species from the “theoretical understanding of the way species exist”, that is, the concept. This idea places the recognition of a species outside the confines of any preconception of how a species should be conceptualised. There is a need for species pluralism, which is the overarching monist concept, and has been the underlying goal of all species conceptual arguments.

A fundamental pluralistic approach seeks to bring an overarching conceptuality to the differing species concepts in which the goal was not an abandonment of any one concept *per se*, but rather an acceptance that each concept is an operational tool to be used in the discovery of the species (Mayden 1999). The determination of the evolutionary trajectory has priority in species demarcation and the species concept applied is merely the tool to enable recognition of that evolutionary event.

One of the major issues that distinguishes species concepts is the determination of where the process of evolutionary separation has been finalised, or is an on-going process marked with a lack of complete biological separation of the populations. There is a growing shift to accept species as evolutionary populations and a realisation that criteria for delimiting these species cannot be restricted, but rather needs to be based on factors that are outside the confines of any one isolating biological property (Naomi 2011). That is, under essentialist pluralism, the taxonomist may be aware of an essential characteristic that makes a species unusual and distinctive. This then forms the basis for a criterion, and the taxonomist is free to determine a conceptual approach that provides the framework for naming a new taxon based on that distinctiveness. Therefore, under essentialist pluralism, there is no restriction on which concept is used to delineate an organism. However, this conceptual freedom demands that taxonomists accept an obligation to be true to the phylogeny and thus must justify the choice of species concept, both in terms of a criterion for distinction, as well as an explanation for the cause of that species existence.

### **Philosophical Failings**

Many of the reviews of species concepts fail to explore essentialist arguments, or when this exploration is carried out, it is with the basic premise that all essentialist arguments are phenetic. However, one of the major failings of the current essentialist approach to species criteria is the decision that species concepts are facts and, therefore, acceptable to be used taxonomically (Hey 2006). This clearly is the crux of the problem. Taxonomists fail to separate the criteria with the distinctive hypothetical process of species delimitation with the rigidity to a concept (Paul 2002). The natural consequence of which explains why the treatment of complex taxonomic clusters, such as agamics, is overlooked in conceptual formulations. It is only with essentialistic pluralism that the taxonomist is freed from the theoretical constraints of taxonomic rigidity imposed by doctrinal adherence to a single species concept and able to explore the criteria necessary to impart taxonomic meaning.

Fundamentally, species need to be conceptualised outside of taxonomic classificatory systems as they fall outside of systematic hierarchical arguments (Dubois 2011). This is because species, although hypothetically chosen, remain real entities, represented by collective individual populations and not just intentional meanings derived by the taxonomist, which is innately what higher classifications are (Ghiselin 1974; Hull 1976). This raises a point of contention: if species are real, why are many of the concepts that are used to define them based on unreal or non-causal criteria? This leads to a complexity in conceptual realisation and invariably to

conceptual misunderstanding, a problem absent in higher taxonomic arguments that have no physical reality (Stamos 2003).

### **Implications for Discerning Species**

Recent evolutionary essentialism has, at its core, a sense of indeterminacy in the definition of what constitutes a species (Devitt 2010). This indeterminacy can be countered if a species is first viewed as an individually unified population representing hypotheses that explain the convergence of both intrinsic and extrinsic structural essences. The acceptance of essences as having intrinsic and extrinsic properties highlights one of the theoretical failings of the current anti-essentialism debate, where species are delineated based primarily on intrinsically pseudo-phenetically inclined parameters (Lewens 2012). The intrinsic and extrinsic structural essences of collective higher taxa particular to a clade are used to form a continuum, the essence matrix, from which the organism state is then delineated. This organism state represents a static cross-section in the evolutionary history of a real population that contains all the phylogenetic restricted character essences that are exhibited by the organism and allows for group delineation (Pleijel and Rouse 2000; figure 1).

The evolutionary progression of the organism is phylogenetically constrained by the evolving and limiting structural essences. This idea of structural essences forming a unified entity is in the true Aristotelian tradition (Dumsday 2012). Notwithstanding, the concept of phylogeny generated by the new evolutionary synthesis necessitates that these structural essences are viewed as spatiotemporally mutable. Therefore, structural essences are to be seen as historical and, possibly, changingly pluralistic in nature and in turn reference the wider immutable spatiotemporal.

### **Conclusion**

The reliance on species relational concepts without an evolutionary context, and the linking of phenetic ideology with the concept of essence, is a failing in much of current essentialist and anti-essentialist arguments (Lewens 2012). It is only with the understanding of the structural essence itself, and with knowledge of the driving forces and processes that gave rise to that essence, which enables the discernment of analogies and reveals the true phylogenesis of an organism. It is how the cladist or taxonomist deals with the delineation of stages in the evolutionary progression of structural essences that then forms the basis of the restriction of the organism state and how the kind is defined. This is then consequently reflected in the criteria used in the choice of model of speciation and conception that is utilised to impart taxonomic meaning to all hypothetical entities called a species.

Once the taxonomist has distinguished the evolutionary trajectory of an organism based on any criterion, there is freedom to determine an appropriate conceptual approach to justify the recognition of the new species. The only requirement that is placed on the taxonomist is the need for explicitness in the justification for that conceptual choice. Essentialistic pluralism generates hypothetical terminal taxonomic units from which phylogenies are then constructed. Therefore, delimitation of species has a critical impact on the understanding of evolutionary biology where they form the spatio-temporal kind within an essence matrix, the continuum of evolutionary descent. The use of essentialistic pluralism, with its unrestricted approach to conceptualisation of

what a species is, allows the taxonomist the freedom to express a unique approach to exploring phylogeny without the shackles of rigid necessity to declare adherence to a single species concept. Essentialist pluralism is, therefore, the gold standard for universality and is the conceptual monist Holy Grail that has underpinned the rhetoric of species debates for centuries. It is only the fear of reputational capital loss by taxonomists who have spent their lives arguing for one concept that implicitly holds essentialistic pluralism back from achieving universal acceptance.

The conceptual monist argument that pluralism leads to confusion through a lack of intrinsic meaning in the term species can be overcome when the taxonomist is explicit. The use of essentialist pluralism delineates a set of organisms from the natural world that contains enough meaning to enable discrimination and thus allow for an organism's taxonomic discernment. It is the failing of hierarchical taxonomic theory that, even if kinds are well defined, there remains a distinct lack of evolutionary theory or the conceptual idea of what the describing author had for the relationships between higher taxa. Therefore, essentialistic pluralism addresses the issue of species demarcation at its core. Once the taxonomist has distinguished the evolutionary trajectory of an organism based on any criterion, there is freedom to determine an appropriate conceptual approach to justify the recognition of the new species. The only requirement that is placed on the taxonomist is the need for explicitness in the justification for that conceptual choice. This invariably makes sub-specific ranks taxonomically meaningless, and invariably recognises all ranks below species as individual evolutionary lines worthy of full species recognition. This leads to an argument for the use of monomial terminal taxonomy. Further, this new taxonomic approach to species conceptualisation has significant implications for the assignment of higher taxonomy, which is often more a reflection of the lack of "room" at the lower cladistic levels under the draconian Linnaean rigid methodology. Essentialistic pluralism and terminal taxonomy present a new approach to species, and are natural extensions of using rank-free phylogenetic taxonomy in higher classification.

The Linnaean system is a set of informal hierarchies that is simply the grouping of organisms into clusters based on taxonomic preference, which are then named relative to each other without the need for historic consideration of any higher relationship. This lack of relational meaning can be traced back to the fact that relational understanding of higher systematics fundamentally eluded Linné. The need to explain evolutionary trends has become an important facet in the modern evolutionary synthesis, and such evolutionary processes and patterns need to be reflected in the nomenclature. This contextual ambiguity has left Linnaean taxonomy struggling to demonstrate true historical relationships between the taxa within clades. Therefore, there is a strategic need to revise the lower order taxonomy and in particular revisit the idea of uninomials to avoid arbitrary cladistics rankings.

Essentialistic pluralism addresses the issue of species demarcation at its core. Once the taxonomist has distinguished the evolutionary trajectory of an organism based on any criterion, there is freedom to determine an appropriate conceptual approach to justify the recognition of the new species. The only requirement that is placed on the taxonomist is the need for explicitness in the justification for that conceptual choice. This invariably makes sub-specific ranks taxonomically meaningless and invariably recognises all ranks below species as individual evolutionary lines worthy of full species recognition. This leads to an argument for the use of terminal taxonomy to be declared to anchor all levels of nomenclature. Further, this new taxonomic approach to species conceptualisation has significant implications for the assignment of higher taxonomy, which is often

more a reflection of the lack of “room” at the lower cladistic levels under the draconian Linnaean rigid methodology. Essentialistic pluralism and terminal taxonomy present a new approach to species and is a natural extension of using rank free of phylogenetic taxonomy in higher classification.

Text Box 1: Glossary of new and revised significant taxonomic terms.

*Organism state* - the phylogenetically constrained boundary of all potentially expressed essences that a biological population (considered a species) exhibits at a static point in its spatiotemporal evolution, that is, a holomorph.

*Kind* - a region within an organism state that represents a conflux of an organism's structural essences, and reflects the nature of an organism at a point in its evolutionary progression, a immutable semaphoront.

*Structural essence* - an evolutionary trait that maybe represent a phenotypically plastic form, or an ecological boundary, which defines an intrinsic or extrinsic aspect of the organism.

*Character essence* - the immutable attribute of an individual that reflect a spatiotemporal expression of structural essences.

*Essence matrix* - the entire collection of structural essences that unifies the ancestral and descendant taxa and is used to define the higher clade from which an organism state has evolved.

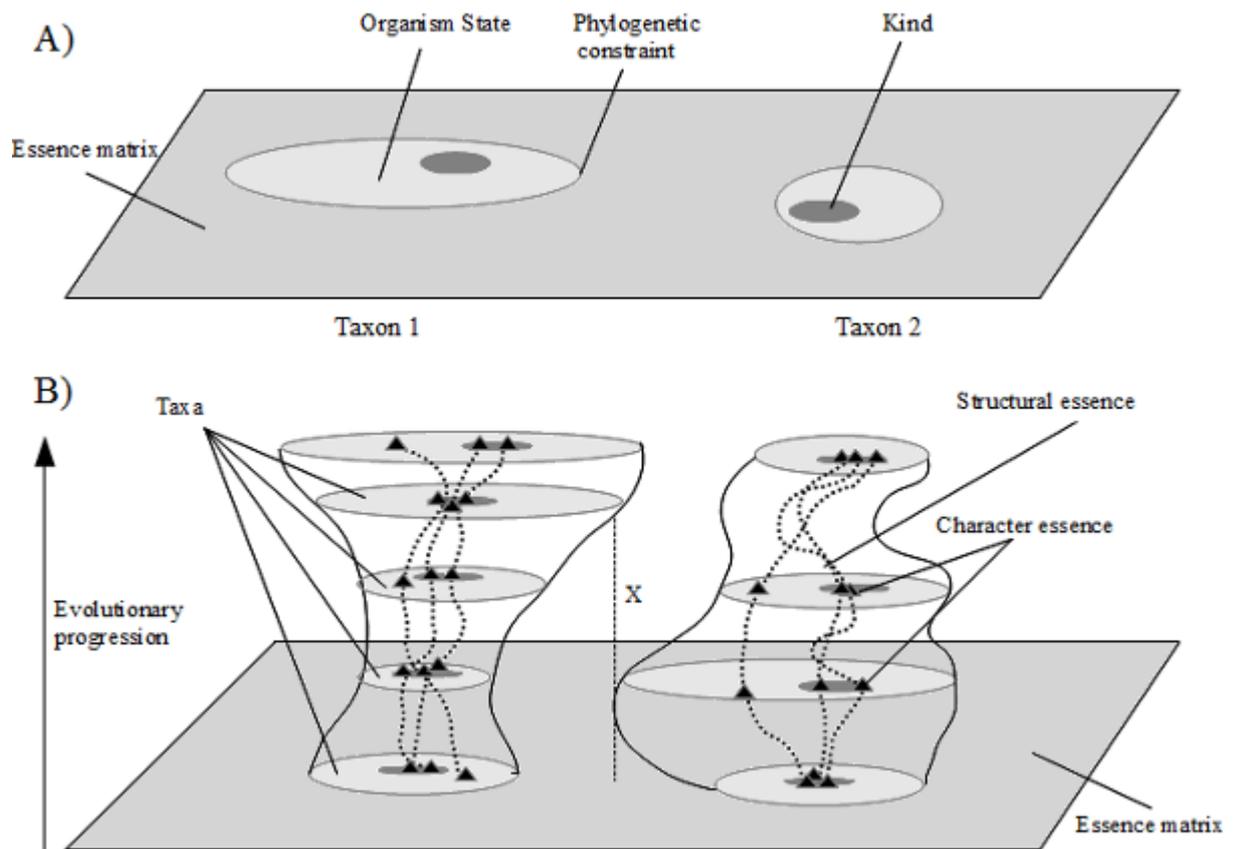

Figure 1: The two fundamental essentialist ideologies: A) the phenetic approach, which does not include evolutionary progression; and B) the essential pluralist approach, in which structural essences are used to delineate an organism state with character essences in temporal stasiogenesis within the evolutionary continuum. Where differing organisms show similar structural essences (X) through mechanisms as a consequence of occupying the same position within the essence matrix arising from mechanisms such as convergence, but can be readily distinguished from each other through an understanding of the evolutionary progression.

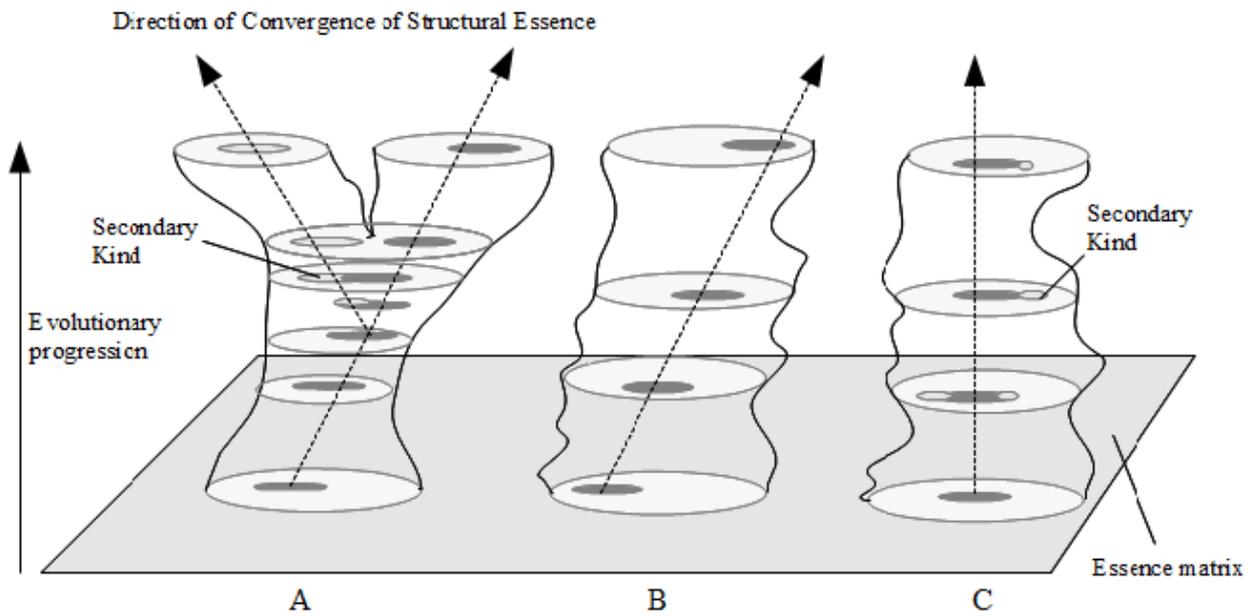

Figure 2: The use of structural essences and the organism state to illustrate how the delineation of a kind can reflect modes of evolutionary phylogenesis: A) cladogenic evolution, in which there are two distinctive kinds created each with individual phylogenetic constraints; B) anagenic evolution, where there is a shift in the structural essence convergence giving rise to distinctive changes in the kind within the relatively constant phylogenetic constraints; and C) stasiogenic evolution, in which there is with no change in the kind, illustrating also that, while the phylogenetic constraints remain relatively stable, there may be reticulation.
